(Received 15 January 1999)

We investigate the amount of communication that must augment classical local hidden variable models in order to simulate the behavior of entangled quantum systems. We consider the scenario where a bipartite measurement is given from a set of possibilities and the goal is to obtain exactly the same correlations that arise when the actual quantum system is measured. We show that, in the case of a single pair of qubits in a Bell state, a constant number of bits of communication is always sufficient—regardless of the number of measurements under consideration. We also show that, in the case of a system of n Bell states, a constant times 2^n bits of communication is necessary.

Bell’s celebrated theorem [1] shows that certain scenarios involving bipartite quantum measurements result in correlations that are impossible to simulate with a classical system if the measurement events are spacelike separated. If the measurement events are timelike separated, then classical simulation is possible, at the expense of some communication. Our goal is to quantify the required amount of communication.

This is part of the broader question of how quantum information affects various resources required to perform tasks in information processing. A two-way classical communication channel between two separated parties can be regarded as a resource, and a natural goal is to select two parties to produce classical information satisfying a specific stochastic property. One question is, if the parties have an a priori supply of quantum entanglement, can they accomplish such goals with less classical communication than necessary in the case where their a priori information consists of only classical probabilistic information? And, if so, by how much? Our question is, to what extent does the fundamental behavior of an entangled quantum system itself provide savings, in terms of communication, compared with classical systems?

Imagine a scenario involving two “particles” that may have been “together” (and interacted) at some previous point in time, but are “separated” (in a sense which implies that they can no longer interact) at the present time. Suppose that a measurement is then arbitrarily selected and performed on each particle (not necessarily the same measurement on both particles). If the underlying physics governing the behavior of the system is “classical” then the behavior of such a system could be based on correlated random variables (usually called “local hidden variables”), reflecting the possible results of a previous interaction. If no communication can occur between the components at the time when the measurements take place then this imposes restrictions on the possible behavior of such a system. In fact, if the underlying physics governing the behavior of the system is “quantum” (in the sense that it can be based on entangled quantum states, rather than correlated random variables) then behavior can occur that is impossible in the classical case. This is a natural way of interpreting Bell’s theorem [1,2]. To formalize—and later generalize—this, we shall define quantum measurement scenarios and (classical) local hidden variable schemes.

Define a quantum measurement scenario as a triple of the form (|ψ⟩_{AB}, M_A, M_B), where |ψ⟩_{AB} is a bipartite quantum state, M_A is a set of measurements on the first component, and M_B is a set of measurements on the second component.

It is convenient to parametrize the simplest von Neumann measurements on individual qubits by points on the unit circle. (More general von Neumann measurements, which involve complex numbers, are considered later in this paper.) Let the parameter x ∈ [0, 2π) denote a measurement with respect to the operator

R(x) = \begin{pmatrix} \cos x & \sin x \\ \sin x & -\cos x \end{pmatrix}

(1)

whose eigenvectors are \cos(x/2)|0⟩ + \sin(x/2)|1⟩ and \sin(x/2)|0⟩ - \cos(x/2)|1⟩.

Consider the case of a pair of qubits in the Bell state |Φ^+⟩_{AB} = \frac{1}{\sqrt{2}}|00⟩ + \frac{1}{\sqrt{2}}|11⟩. (Our results are written for such states, but can be modified to apply to any of the other Bell states, including the Einstein-Podolsky-Rosen singlet state |Ψ^−⟩_{AB} = \frac{1}{\sqrt{2}}|01⟩ - \frac{1}{\sqrt{2}}|10⟩.) Let x, y ∈ [0, 2π) be the respective measurement parameters of the two components and let a, b ∈ {0, 1} be the respective outcomes. Then the joint probability distribution of these outcomes is given as

\begin{align*}
\Pr[a = 0] &= \frac{1}{2} \cos^2\left(\frac{x}{2}\right) + \frac{1}{2} \sin^2\left(\frac{y}{2}\right) \\
\Pr[a = 1] &= \frac{1}{2} \sin^2\left(\frac{x}{2}\right) + \frac{1}{2} \cos^2\left(\frac{y}{2}\right)
\end{align*}
Two simple but noteworthy examples of bipartite quantum measurement scenarios with the Bell state \((\Phi^+)_{AB}\) are as follows: Example 1, \((\Phi^+)_{AB}, M_A, M_B\), where \(M_A = M_B = \{0, \pi\}\). Example 2, \((\Phi^+)_{AB}, M_A, M_B\), where \(M_A = \{-\frac{\pi}{8}, \frac{3\pi}{8}\}\) and \(M_B = -M_A = \{\frac{\pi}{8}, -\frac{3\pi}{8}\}\). In both examples, each individual outcome is a uniformly distributed bit regardless of the measurements. In Example 1, if the two measurements are the same then the outcomes are completely correlated, whereas if the two measurements are different, the outcomes are completely independent. In Example 2, the two outcomes are equal with probability \(\sin^2(\frac{\pi}{8})\) if \(x = y = +\frac{3\pi}{8}\), and with probability \(\cos^2(\frac{\pi}{8})\) otherwise. These examples are interesting in the context of local hidden variable schemes, which are defined next.

Intuitively, we are interested in classical devices that simulate bipartite quantum measurement scenarios to varying degrees, and such devices are naturally explained as local hidden variable schemes. To define a local hidden variable scheme, it is convenient to view it as a two-party procedure whose execution occurs in two stages: a preparation stage and a measurement stage. For ease of reference, we call the two parties Alice and Bob. During the preparation stage, local hidden variables \(u\) for Alice and \(v\) for Bob are determined by a classical random process. During this stage, arbitrary communication can occur between the two parties, so \(u\) and \(v\) may be arbitrarily correlated. During the measurement stage, measurements \(x\) and \(y\) are given to Alice and Bob, respectively, who produce outcomes \(a = A(x, u)\) and \(b = B(y, v)\), respectively. During this stage, no communication is permitted between the parties, which is reflected by the fact that the value of \(A(x, u)\) is independent of the value of \(y\) (and vice versa).

A local hidden variable scheme simulates a measurement scenario \((|\Psi\rangle_{AB}, M_A, M_B)\) if, for any \(x \in M_A\) and \(y \in M_B\), the outputs produced by Alice and Bob (namely, \(a\) and \(b\), respectively) have exactly the same bivariate distribution as the outcomes of the quantum measurement scenario as dictated by the laws of quantum physics.

The measurement scenario in Example 1 is easily simulated by the following local hidden variable scheme. Let \(u\) and \(v\) each consist of a copy of the same uniformly distributed two-bit string. Then let Alice and Bob each output the first bit of this string if their measurement is 0 and the second bit if their measurement is \(\pi/2\). On the other hand, for the measurement scenario of Example 2, it turns out that there does not exist a local hidden variable scheme that simulates it [2].

Now, we consider a more powerful classical instrument for simulating measurement scenarios. Define a local hidden variable scheme augmented by \(k\) bits of communication as follows. Informally, it is a local hidden variable scheme, except that the prohibition of communication between the parties during the measurement stage is relaxed to a condition that allows up to \(k\) bits of communication. More formally, a local hidden variable scheme augmented by \(k\) bits of communication has a preparation stage where random variables \(u\) and \(v\) for Alice and Bob are determined and during which arbitrary communication is permitted between the two parties. Then there is a measurement stage which begins by measurements \(x\) and \(y\) being given to Alice and Bob, respectively. One party then computes a bit (as a function of his/her measurement and local hidden variables) which is sent to the other party. This constitutes one round of communication. Then, again one party (the same one or a different one) computes a bit (as a function of his/her measurement, local hidden variables, and any data communicated from the other party at previous rounds) and sends it to the other party. This continues for \(k\) rounds, after which Alice and Bob output bits \(a\) and \(b\), respectively.

For example, for the measurement scenario of Example 2, a local hidden variable scheme augmented with one single bit of communication can simulate it. This is a consequence of the following more general result, whose easy proof is left as an exercise.

**Theorem 1.**—For any quantum measurement scenario \((|\Psi\rangle_{AB}, M_A, M_B)\), there exists a local hidden variable scheme augmented with \(\log_2(|M_A|)\) bits of communication (from Alice to Bob) that exactly simulates it.

We shall see that in some cases the upper bound of theorem 1 is asymptotically tight while in other cases it is not. In what follows, we focus on the case of a single Bell state and the case of \(n\) Bell states, and provide a new upper or lower bound in each case.

Consider the case of a single Bell state \(|\Phi^+\rangle_{AB} = \frac{1}{\sqrt{2}}|0\rangle|0\rangle + \frac{1}{\sqrt{2}}|1\rangle|1\rangle\), but where the sizes of \(M_A\) and \(M_B\) may be arbitrarily large. By theorem 1, we obtain only an upper bound of \(\log_2(|M_A|)\) bits for the amount of communication necessary for an augmented local hidden variable scheme to simulate it. In the case where \(M_A\) and \(M_B\) are each the entire interval \([0, 2\pi]\), this communication upper bound would be infinite. If only a finite number \(k\) of bits of communication are permitted, then one alternative that might seem reasonable is for Alice to send \(x'\), a \(k\)-bit approximation of \(x\), to Bob. The protocol for Alice and Bob would be along the lines of the one implicit in theorem 1, but using \(x'\) in place of \(x\). This would clearly not produce an exact simulation for a general \(x \in [0, 2\pi]\), but it would produce an approximation that improves as \(k\) increases. Is this the best that can be done with \(k\) bits of communication? The next theorem demonstrates that it is possible to obtain an exact simulation for any \(x, y \in [0, 2\pi]\) with only a constant number of bits of communication.

**Theorem 2.**—For the quantum measurement scenario \((|\Phi^+\rangle_{AB}, M_A, M_B)\) with \(|\Phi^+\rangle_{AB} = \frac{1}{\sqrt{2}}|0\rangle|0\rangle + \frac{1}{\sqrt{2}}|1\rangle|1\rangle\) and \(M_A = M_B = [0, 2\pi]\), there exists a local hidden variable scheme augmented with four bits of communication (from Alice to Bob) that exactly simulates it.
Proof.—The local hidden variables are \( c \in \{0, 1\} \) and \( \theta \in [0, \frac{3\pi}{4}) \), and both are uniformly distributed.

For \( j \in \{0, 1, \ldots, 9\} \), define \( \alpha_j = \frac{j\pi}{5} \). It is useful to view \( \alpha_0, \alpha_1, \ldots, \alpha_9 \) as ten equally spaced points on the unit circle. Define the \( j \)th \( \alpha \) slot as the interval \( [\alpha_j, \alpha_{(j+1) \mod 10}] \). Also, define \( \beta_0 = \alpha_0 + \theta, \beta_1 = \alpha_3 + \theta \), and \( \beta_2 = \alpha_6 + \theta \), and \( \gamma_0 = \alpha_5 + \theta, \gamma_1 = \alpha_8 + \theta \), and \( \gamma_2 = \alpha_1 + \theta \) (where the addition is understood to be modulo \( 2\pi \)). Define the \( j \)th \( \beta \) slot as the interval \( [\beta_j, \beta_{(j+1) \mod 3}] \), and the \( j \)th \( \gamma \) slot as the interval \( [\gamma_j, \gamma_{(j+1) \mod 3}] \).

The protocol starts by Alice sending Bob information specifying the \( \alpha \) slot, \( \beta \) slot, and \( \gamma \) slot in which \( x \) is located. Note that these slots partition the unit circle into sixteen intervals, so Alice can convey this information by sending four bits to Bob. Then Alice outputs the bit \( c \).

The full procedure for Bob is summarized below. Let \( u \) be the interval \([0, \frac{3\pi}{10})\). Note that this event is independent and uniformly distributed on \( [0, \frac{3\pi}{10}) \). The local hidden variables are \( a, b, c \).

To analyze the stochastic behavior of this procedure (still in the special case), let \( r = |x - y| \) and note that
\[
\text{Pr}[a = b] = \cos^2 \left( \frac{x + y'}{2} \right) \cos^2 \left( \frac{x - y}{2} \right).
\]
which is exactly what is required.

The procedure for Bob in the above special case can be generalized to apply to the other possible cases by considering various similarities and symmetries among the cases. Once Bob obtains information from Alice that specifies the \( \alpha \) slot, \( \beta \) slot, and \( \gamma \) slot of \( x \), he simply has to apply the following procedure, shown below in pseudocode:

If the difference between the \( \alpha \)-slot numbers of \( x \) and \( y \) is more than 2, then
set \( y \) to \( y + \pi \).

If the \( \alpha \)-slot number of \( y \) is in \( \{7, 8, 9, 0, 1\} \), then
set \( \beta_0, \beta_1, \beta_2 \) to \( \gamma_0, \gamma_1, \gamma_2 \).

If \( x \) and \( y \) are in the same \( \beta \)-slot, then
output \( c \).

Otherwise, there exists a \( \beta_k \) between \( x \) and \( y \)
such that \( |y - \beta_k| \) is a \( \beta_k \) slot with probability \( 1 - \frac{3\pi}{10} \sin(u) \).

Theorem 2 applies to all measurements with respect to operators of the form given in Eq. (1). The most general possible von Neumann measurement on an individual qubit can be parametrized by \( (x, x') \) and \( (y, y') \), and \( a \) and \( b \) are the respective outcomes, then
\[
\text{Pr}[a = 0] = \text{Pr}[b = 0] = \frac{1}{2} \text{ and }\n\text{Pr}[a = b] = \cos^2 \left( \frac{x' + y'}{2} \right) \cos^2 \left( \frac{x - y}{2} \right) + \sin^2 \left( \frac{x' + y'}{2} \right) \cos^2 \left( \frac{x + y}{2} \right).
\]

Theorem 3.—For the quantum measurement scenario \( (|\Phi^+\rangle_{AB}, MA, MB) \) with \( |\Phi^+\rangle_{AB} = \frac{1}{\sqrt{2}} |0\rangle |0\rangle + \frac{1}{\sqrt{2}} |1\rangle |1\rangle \) and \( MA = MB = [0, 2\pi) \times [0, 2\pi) \), there exists a local hidden variable scheme augmented with eight bits of communication (from Alice to Bob) that exactly simulates it.

Proof.—The local hidden variable scheme consists of two executions of the four-bit protocol of theorem 2. In the first execution, Alice and Bob use measurement parameters \( x' \) and \( -y' \) to obtain output bits \( a' \) and \( b' \) such that
\[
\text{Pr}[a' = b'] = \cos^2 \left( \frac{x' + y'}{2} \right).
\]
In the second execution, Alice and Bob use measurement parameters \( (-1)^a x \) and \( (-1)^b y \) to obtain their final output bits \( a \) and \( b \), respectively. Note that
\[
\text{Pr}[a = b] = \begin{cases} \cos^2 \left( \frac{x - y}{2} \right) & \text{if } a' = b' \\ \cos^2 \left( \frac{x + y}{2} \right) & \text{if } a' \neq b' \end{cases},
\]
which, combined with Eq. (5), implies Eq. (4).
implies that any $n$ independent von Neumann measurements performed on the $n$ Bell states can be simulated by a local hidden variable scheme augmented with $8n$ bits of communication. In the case of coherent measurements on such a state, the exact simulation cost can be much larger, as shown by the following theorem.

**Theorem 4.**—There exists a pair of sets of measurements, $M_A$ and $M_B$ (each of size $2^2$) on $n$ qubits, such that, for the quantum measurement scenario $(|\Phi^+\rangle_{AB}, M_A, M_B)$ with $|\Phi^+\rangle_{AB} = \frac{1}{\sqrt{2}} \sum_{i \in \{0,1\}^n} |i\rangle \langle i|$, any local hidden variable scheme must be augmented with a constant times $2^n$ bits of communication in order to exactly simulate it.

Proof. —The proof is based on connections between a measurement scenario and a communication complexity problem examined in [3]. We begin by defining a set of $2^n$ measurements, which we call Deutsch-Jozsa measurements, due to their connection with the algorithm in [4]. The measurements are parametrized by the set $\{0,1\}^2$. For a parameter value $z \in \{0,1\}$, we index the bits of $z$ by the set $\{0,1\}^n$. That is, for $i \in \{0,1\}^n$, $z_i$ denotes the “ith” bit of $z$. The measurement on $n$ qubits corresponding to $z \in \{0,1\}^2$ is easily described as two unitary transformations followed by a measurement in the computational basis. The first unitary transformation is a phase shift that maps $|i\rangle$ to $(-1)^{i\cdot j} |i\rangle$ for each $i \in \{0,1\}^n$. The second unitary transformation is the n-qubit Hadamard transformation, which maps $|i\rangle$ to

$$
\frac{1}{\sqrt{2^n}} \sum_{j \in \{0,1\}^n} (-1)^{i \cdot j} |j\rangle,
$$

where $i \cdot j$ is the inner product of the two $n$-bit strings $i$ and $j$ (that is, $i \cdot j = i_0 j_0 + i_1 j_1 + \cdots + i_{n-1} j_{n-1}$).

These two unitary transformations are followed by a measurement in the computational basis $\{|i\rangle: i \in \{0,1\}^n\}$, yielding an outcome in $\{0,1\}^n$.

Set $M_A = M_B = \{0,1\}^2$, the set of Deutsch-Jozsa measurements. It is straightforward to show that, for $x \in M_A$ and $y \in M_B$, the joint probability distribution of the outcomes $a$ and $b$ satisfies the following properties:

1. If $x = y$, then $\Pr[a = b] = 1$.
2. If the Hamming distance between $x$ and $y$ is $2^{n-1}$, then $\Pr[a = b] = 0$.

We now reduce a communication complexity problem in [3] to the problem of designing an augmented local hidden scheme that satisfies properties 1 and 2. The communication complexity problem (called EQ' in [3]) is a restricted version of the “equality” problem, and is defined as follows. Alice and Bob get inputs $x, y \in \{0,1\}^2$, respectively, and one of them (say, Bob) must output 1 if $x = y$ and 0 if the Hamming distance between $x$ and $y$ is $2^{n-1}$. The output of Bob can be arbitrary in all other cases. In [3], it is shown that any classical protocol that exactly solves this restricted equality problem requires $c2^n$ bits of communication for some constant $c > 0$ and all sufficiently large $n$. The proof is based on a combinatorial result in [5]. Suppose that there exists a local hidden variable scheme augmented with $f(n)$ bits of communication that simulates the measurement scenario $(|\Phi^+\rangle_{AB}, M_A, M_B)$. One can then use this to construct a protocol for restricted equality with $f(n) + n$ bits of communication as follows. Alice and Bob first execute the protocol for $(|\Phi^+\rangle_{AB}, M_A, M_B)$ and then Alice sends her output $a$ to Bob, who outputs 1 if $a = b$ and 0 if $a \neq b$. It follows that $f(n) + n \geq c2^n$, so $f(n) \geq c2^n - n \geq c2^n$, for some $c > 0$ and sufficiently large $n$.

The theorem extends to all $n \geq 1$, possibly using a smaller constant $c'$, because it follows from [2] that example 2 cannot be simulated without communication.

In conclusion, we have shown how to exactly simulate the behavior of a bipartite entangled quantum system consisting of two qubits prepared in a Bell state: eight bits of classical communication suffice to reproduce exactly the correlations that arise when the qubits are independently subjected to arbitrary von Neumann measurements. In contrast, the exact simulation of the behavior of a bipartite quantum system consisting of $n$ Bell states requires an amount of communication that is exponential in $n$.

Similar work was carried out independently by Michael Steiner [6]. Using a different technique, he showed how 1.49 classical bits of communication suffice on the average for the quantum measurement scenario $(|\Phi^+\rangle_{AB}, M_A, M_B)$ with $|\Phi^+\rangle_{AB} = \frac{1}{\sqrt{2}} (|0\rangle|0\rangle + |1\rangle|1\rangle)$ and $M_A = M_B = \{0,2\pi\}$ that we consider in theorem 2. It follows from the techniques used in our proof of theorem 3 that 2.98 bits of classical communication suffice on the average to simulate the behavior of arbitrary von Neumann measurements carried out independently on two qubits prepared in a Bell state. Although this is better than the eight bits that we need in this Letter, Steiner’s technique imposes no upper limit on the number of bits that need be communicated in the worst case.
